Abstract: Zinc zirconate nanocomposites with varying compositions of Dy^{3+} ions were synthesized through a solution combustion method using citric acid as a fuel. There were mixed hexagonal ZnO and cubic ZrO_2 phases in the X-ray diffraction patterns of the composites whose average crystallite sizes range between 27 and 38 nm. Scanning electron microscopy images show a mixture of polygonal and hexagonal rod-like structures of varying aggregation levels at the different Dy^{3+} -doping concentrations. The reflectance spectra showed absorption edges around 400 nm and an energy bandgap between 2.99 and 3.07 eV. There was a violet emission from the host matrix that gradually shifted towards white light with enhanced doping. At a higher Dy^{3+} concentration, there was luminescence quenching attributed to dipole-dipole interaction among the dopant ions. The synthesized nanocomposite phosphors may be used in sensors and colored display technology.

1. Introduction

Zinc zirconate nanocomposites have been applied in dye-sensitized solar cells (DSSCs) as well as in the photocatalytic removal of textile dyes [1–4]. Nanocomposites exhibit more enhanced properties than those inherent in the individual constituent compounds. These properties are usually dominated by the interface or interphase characteristics [5,6]. In the zinc zirconate nanocomposites, the different percentages of ZnO and ZrO_2 compounds significantly affect the applications of the material [7]. In the nanocomposite, zinc oxide (ZnO) has been observed to enhance the conductivity and stability of the material [8]. Zinc oxide has drawn a lot of research attention due to its possible application in solar cells and water purification among other interests [2,3,9–11]. Further, the oxide has been used in chemical gas sensors, the removal of environmental contaminants and in photocatalysis. Due to its anti-bacterial activity, zinc oxide is used in the production of cosmetics and sunscreens [12].

The ninth most abundant substance in the earth's crust, zirconium, forms three major oxide phases; namely monoclinic, tetragonal and the cubic phase [13]. The properties of zirconium oxide (zirconia) depend on the phase that is present in a particular material. The thermal and chemical stability of zirconia coupled with excellent photophysical characteristics make it useful in the ceramics industry, dentistry, piezo-electric devices and as an electrolyte for electrochromic devices. With a high refractive index of about 2.18, zirconia is also used as a gemstone [13–16]. Due to a tunable wide bandgap of up to 6.4 eV, zirconia phosphors are a good host matrix for rare-earth ions and hence useful in light emitting applications as well as in high-temperature thermometry [17,18].

Rare earth metal dopants are used in semiconductor nanocomposites in order to influence their structural and optical properties [15,19,20]. Dysprosium is a rare earth metal used in making contrast agents for magnetic resonance imagery and the production of permanent magnets for electric cars as well as direct-drive wind mills. It is also used in the manufacture of multi-layer ceramic capacitors and data storage materials such as computer hard disc drives [21–23].

The most traditional route for preparing perovskite nanomaterials is the solid-state reaction method. Nevertheless, ceramic material oxides prepared using this conventional method have shown inhomogeneity through uncontrolled and irregular particle morphologies [24,25]. In the recent past, there has been increased uptake of wet chemical synthesis methods. By reducing the diffusion path, wet chemical methods ensure molecular level mixing of each of the constituent compounds to the nanoscale. These methods have been used in the synthesis of semiconductor oxides of high crystallinity at lower temperatures in comparison to the conventional solid-state reactions [26].

Among the wet chemical methods, solution combustion synthesis (SCS) is an effective route for the synthesis of nanoparticles. Once heated, the precursor mixture results in a self-sustaining exothermic reaction, in which the reactants self-ignite. This method has gained prominence due to the simplicity of equipment and the refinement of the resultant nanocrystals [17,27–32]. Studies have reported the synthesis of zinc zirconate nanocomposites by sol-gel [4,7,33] and hydrothermal [34] techniques. This study sought to investigate the optical and structural characteristics of dysprosium-doped zinc zirconate nanocomposites, synthesized by citric acid - assisted solution combustion process which to the best of our knowledge, has not yet been investigated nor reported.

2. Experiment

2.1. Synthesis

The composite was synthesized using 80 wt. % zirconium butoxide in 1-butanol from Aldrich alongside 98% zinc nitrate, analytical grade nitric acid and ammonia solution from Merck. Details of the synthesis route used in the preparation of the composites are outlined in our earlier work [35,36]. The zirconium (IV) butoxide was reacted with concentrated nitric acid to produce a solution of zirconium nitrate. The solution was diluted with 50 ml of de-ionized water and then mixed with 0.03 M zinc nitrate. Six samples were made by mixing the solutions with varying percentages of dysprosium nitrate, constituting 0, 1, 2, 3, 4 and 5% Dy^{3+} ions per mole. Citric acid fuel which acted as a complexant, was added to each of the mixtures and then the pH adjusted, while stirring using ammonia solution to 7. In each case, the precursor mixture was heated until spontaneous flaming occurred as a result of self-combustion. Using a mortar and pestle, the resultant fluffy composite powders were ground, then calcined at 600 °C for 2 hours.

2.2. Characterization methods

X-ray diffraction (XRD) measurements on the composite were done using a Bruker D8 X-ray diffractometer whose wavelength, $K\alpha = 0.15406$ nm. The angle of diffraction, 2θ was varied between 10° and 70° in steps of 0.03° per minute. Ultraviolet/visible (UV-vis) measurements were performed using a Lambda 950 PerkinElmer UV WinLab Spectrophotometer while photoluminescence measurements were done with a Hitachi Spectrophotometer, Model number F-7000 FL. The morphology studies were carried out using a Jeol JSM-7800F Field Emission Scanning Electron Microscope (FESEM) equipped with Oxford Aztec EDS and Gatan Mono CL4.

3. Results and discussion

3.1. X-ray diffraction analysis

Figure 1 shows XRD patterns of the synthesized nanocomposite mixtures of the cubic zirconia and the hexagonal zinc oxide phases that correspond to ICDD cards 81-1551 and 75-1526, respectively. From the figure, it was observed that the zirconia peaks were comparatively broader and more intense than the zinc oxide peaks. The enhanced peak intensity on increased doping was probably due to the more preferentially oriented reflecting surface planes that resulted from an increased density of the zirconia crystallites [37,38].

Fig. 1. XRD patterns of the Dy^{3+}-doped nanocomposites.

Figure 2 shows the peak shifts against the dopant concentrations. For each of the phases in the composite, there was an initial shift towards lower angles as a result of the incorporation Dy^{3+} at the cations sites. It was expected that the substitution of either Zn^{2+} or Zr^{4+} ions by the Dy^{3+} dopant would cause a distortion in the crystal and hence strain the lattice. Further, there would be a need for charge compensation due to the valence difference between the dopant and the substituted cations, leading to oxygen vacancy defects.

In the hexagonal ZnO, the Zn^{2+} ions are tetrahedrally coordinated by four O^{2-} ions while the Zn^{2+} ions coordinating each O^{2-} ion is four. Therefore, its coordination number (CN) in the structure is 4, and the ionic radii for the Zn^{2+} and Dy^{3+} ions at $CN = 4$ are equal to 0.60 Å and 0.78 Å, respectively [39,40]. Similarly, the cubic ZrO_2 structure has Zr^{4+} coordinated by 6-oxygen atoms and the Zr^{4+} ionic radii is 0.72 Å while that of Dy^{3+} is 0.91 Å [40]. The
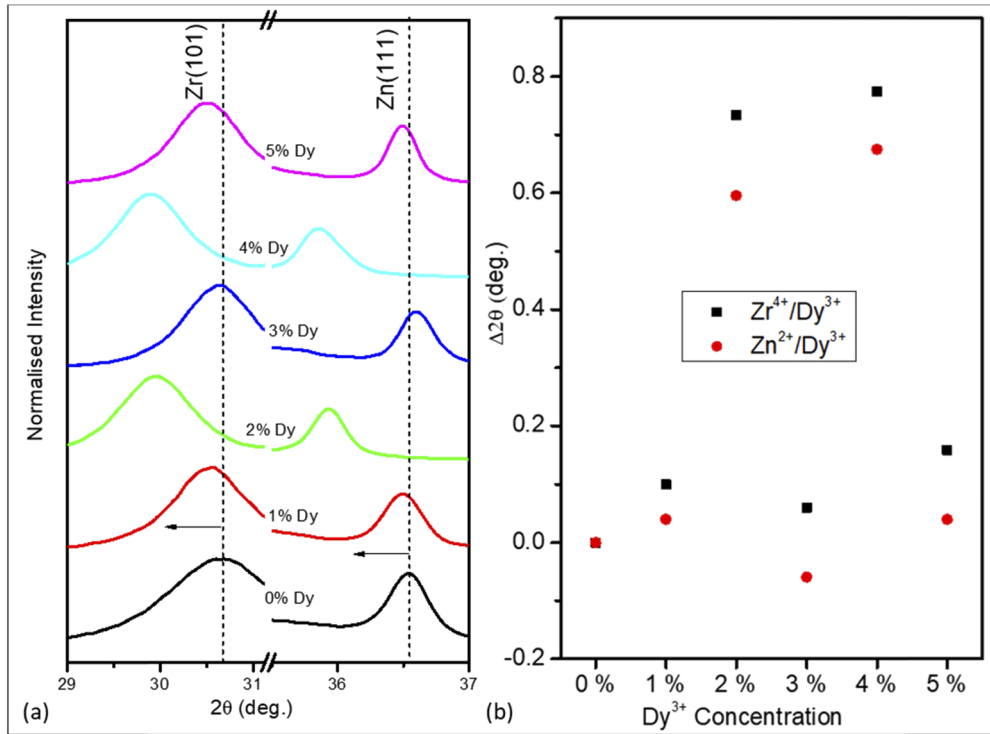

Fig. 2. (a) Illustration of (111) ZnO/Dy^{3+} & (101) ZrO$_2$/ Dy^{3+} peak shifts and (b) difference in peak shifts for ZrO$_2$ and ZnO, respectively for various Dy^{3+} ion concentrations.

differences in ionic radii between Zn^{2+}/Dy^{3+}, and Zr^{4+}/Dy^{3+} are 0.18 Å and 0.19 Å, respectively. These values are, however, are too close to pinpoint the substitution site for the Dy^{3+} dopant ions.

Earlier studies have shown that the radius percentage difference between dopant and the host ions should not be greater than 30%. For the nanocomposite, the difference in the percentage radius, r_i between the dopant ion (Dy^{3+}) and the host ions (Zn^{2+}) in ZnO and (Zr^{4+}) in ZrO$_2$, were evaluated using the relation [41,42];

$$r_i = \frac{r_h - r_d}{r_i} \times 100 \ \% \tag{1}$$

where r_h is the host radius (Zn^{2+} or Zr^{4+}) and r_d is the radius of the Dy^{3+} dopant ion, at the coordination number, *CN*. When a Dy^{3+} ion substitutes a Zn^{2+} ion, the value of r_h is 30% and 26% when on a Zr^{4+} site. Therefore, the Dy^{3+} dopant will preferentially substitute the Zr^{4+} ions in the nanocomposite lattice because of the smaller radius percentage difference, despite the ionic radius difference. This is correlated by Fig. 2(b), which shows that with the incorporation of the Dy^{3+} in the nanocomposite structure, the ZrO$_2$ lattice is more distorted than that of ZnO.

The composite crystallite sizes and their corresponding lattice strains were determined using the relationships [43–46];

$$\beta_\varepsilon = 4\varepsilon \ tan\theta \tag{2}$$

$$\beta_D = \frac{k\lambda}{D \ cos\theta} \tag{3}$$

where *D* is the average size of the crystallites, ε is the micro-strain in the lattice, *k* is a shape dependent dimensionless factor, λ is the wavelength of the X-rays used, θ is the Bragg's angle of diffraction while β_ε and β_D are the micro-strain and crystal size profile broadening, respectively.

These crystallite parameters were obtained using the following four most intense peaks in each phase; ZnO (100), (002), (101), (110) and ZrO_2 (111), (220), (311), (200). Table 1 shows the average crystallite size, micro-strain, lattice constants and the volume of the unit cell of the nanocomposites as calculated from those peaks [25,47]. Generally, the substitution of the larger ion (Dy^{3+}) at the sites of smaller ions (Zr^{4+} & Zn^{2+}) in the lattice caused an enlargement of the lattice and hence an increase in average crystallite size. The table shows that there were small deviations in the calculated values of the lattice constants and the volume of the unit cell for the Dy^{3+}- doped nanocomposites against those of the undoped sample, which were attributed to the local distortions on the crystal structures. The enlargement of the unit cell volume for the doped samples in comparison with the undoped sample is a confirmation of the presence of the Dy^{3+} on both cation sites in the nanocomposite lattice. Table 1 further reveals that the lattice strain of the nanocomposite samples decreases with increasing Dy^{3+} concentration (although non-monotonically). The occupation of Dy^{3+} ions on the tetrahedral sites of the host cations is therefore, expected to increase the lattice strain of the nanocomposite as a result of the difference in radii. The uneven redistribution of strain in the component lattices of the nanocomposite is attributed to lattice distortions arising from the change of the morphology of the particles [48].

Table 1. Values of the average crystallite size, lattice parameters and induced lattice strain of the nanocomposites

Sample	Nanocomposite Crystal size (nm)	Lattice Parameters ZnO			Lattice Parameters ZrO_2		Crystal Strain, ε (10^{-3})	
		a(Å)	c(Å)	V(^{3})	a(Å)	V(^{3})	ZnO	ZrO_2
0% Dy	27.1	3.210	5.560	49.613	5.069	130.247	2.76	7.40
1% Dy	28.9	3.156	5.466	47.149	5.075	130.710	2.47	5.96
2% Dy	33.8	3.257	5.641	51.814	5.144	136.114	2.07	6.18
3% Dy	29.6	3.263	5.652	52.121	5.150	136.591	2.14	6.26
4% Dy	38.3	3.213	5.565	49.755	5.081	131.174	1.75	5.71
5% Dy	32.4	3.205	5.551	49.367	5.069	130.247	1.84	6.22

3.2. Composition and morphology studies

Figure 3 presents some Energy Dispersive X-ray Spectroscopy (EDS) spectra, that were selected to represent the host and doped samples of the nanocomposites. For the undoped sample in Fig. 3(a), the spectrum displays the presence of Zn, Zr, O peaks while the spectrum for the Dy^{3+}- doped sample (Fig. 3(b)) shows Dy peaks in addition to the other elements. The preferential substitution of Zr by Dy is confirmed by the reduced atomic percentage of Zr in the doped sample. It was also observed that there were no other impurity peaks present in the samples, apart from a carbon peak due to the tape used for holding the samples during the measurements.

Figure 4(a-f) present SEM images of Dy^{3+}-doped nanocomposite samples at the various dopant concentrations. Figure 4(a) shows well dispersed polygonal-shaped particles in the undoped nanocomposite. The images for the samples doped with Dy^{3+} at 1% and 3% in Fig. 4(b), (d) show similar characteristics with those of the undoped sample except that the particulates were more populated and compact than in Fig. 4(a). At 2% Dy^{3+} doping, Fig. 4(c) shows an agglomeration of vertically erect hexagonal rods. At 4% Dy^{3+}-doping (Fig. 4(e)), the particles transform into well packed aggregates of eroded polygons similar to those at 5% Dy^{3+} doping in Fig. 4(f), although the latter has smaller crystals that are less agglomerated. It was observed from the SEM images that inadequate or excess dopant concentration inhibits the growth of compact crystal structures. The variation of the morphology with doping was attributed to the lowering of the surface energy of the particles as well as the distortion of grain shapes [49,50].

Fig. 4. SEM images of the nanocomposites with (a) 0%, (b) 1%, (c) 2% (d) 3% (e) 4% and (f) 5% of Dy^{3+} in the nanocomposite.

3.3. Diffuse reflectance spectroscopy

Figure 5(a) shows diffuse reflectance spectra of the nanocomposites. The non-monotonic variation in the reflectance as the dopant concentration changes showed absorption edges around 400 nm. By evaluating the Kubelka-Munk function, $F(R) = \frac{(1-R)^2}{2R}$ together with Tauc's relation on the spectra, the energy bandgap of the nanocomposites was determined [45,46]; For direct transition bandgap materials,

$$F(R)h\upsilon = \alpha_0(h\upsilon - E_g)^{1/2} \tag{4}$$

where R, $h\upsilon$, α_0, and E_g represent the absolute reflectivity, photon energy, absorption coefficient, and optical energy bandgap, respectively. As illustrated in Fig. 5(b), E_g was obtained by plotting $[F(R)h\upsilon]^2$ against $h\upsilon$ and then extrapolating the linear section of the curve to the $h\upsilon$-axis, the point where $[F(R)h\upsilon]^2 = 0$. The energy bandgaps were obtained as 3.07, 3.01, 3.04, 2.99, 3.03 and 3.04 eV for 0%, 1%, 2%, 3%, 4% and 5% Dy^{3+} concentrations, respectively. These bandgaps represented a trend which is in agreement with that of the crystallite sizes in Table 1.
Fig. 5. (a) UV-vis reflectance spectra (b) a plot of the Kubelka-Munk function of the composite.

The declined energy bandgap of all doped samples relative to the undoped nanocomposite is an indication that Dy^{3+} formed energy states within the host bandgap. Generally, energy levels within the bandgap create shallow donor level of impurities near the edge of the conduction band while the levels near the valence band edge are created by shallow acceptor impurities. This means that there is an increase of the density of states of these dopant ions as the amount of doping increases, which effectively reduces the bandgap by the formation of a continuum of states, just as in the bands [51].

3.4. Photoluminescence spectroscopy

Figure 6(a) shows the photoluminescence excitation and emission spectra determined at various wavelengths for undoped zinc zirconate nanocomposite. The excitation spectra obtained by examining the sample at 406, 481 and 580 nm wavelengths shows three peaks. The dominant excitation peak observed at 211 nm was attributed to Zr^{4+} - O^{2-} charge transfer band, while those at 275 and 400 nm are due to defect levels in the host [52]. The presence of the host excitation peaks when monitoring the emission from Dy^{3+} at 481 and 580 nm is an indication that the host lattice is transferring energy to the dopant ions. The emission spectra of the undoped nanocomposite in Fig. 6(a) was obtained by exciting the samples at 211 and 275 nm. The spectra present a broad exciton emission peak centered at 406 nm, ascribed to intrinsic defects within the ZnO and ZrO_2 lattices. The Gaussian fit of the broad band in Fig. 6(b) shows four overlapping peak maxima at 356, 406, 434 and 500 nm. The peaks at 356 and 500 nm were attributed to the near band and the V_o/O_i induced state emissions in ZnO, respectively [53]. Selvam et al. [54] attributed the 406, 434 and 500 nm to deep trap state emissions due to the recombination of the electron−hole pairs from localized deep level states in the bandgap. An estimate of the energy bandgap from PL at the host emission of 406 nm has a value of 3.05 eV for the undoped sample, which agrees quite well with the values obtained from UV spectroscopy in Fig. 5(b).

Figure 7(a) shows the excitation spectra at 481 nm while (b) shows the emission spectra of the Dy^{3+} -doped nanocomposites excited at 211 nm. Just as in the undoped samples, the excitation spectra have three peaks at 211, 275 and 400 nm. The emission spectra consist of the host emission
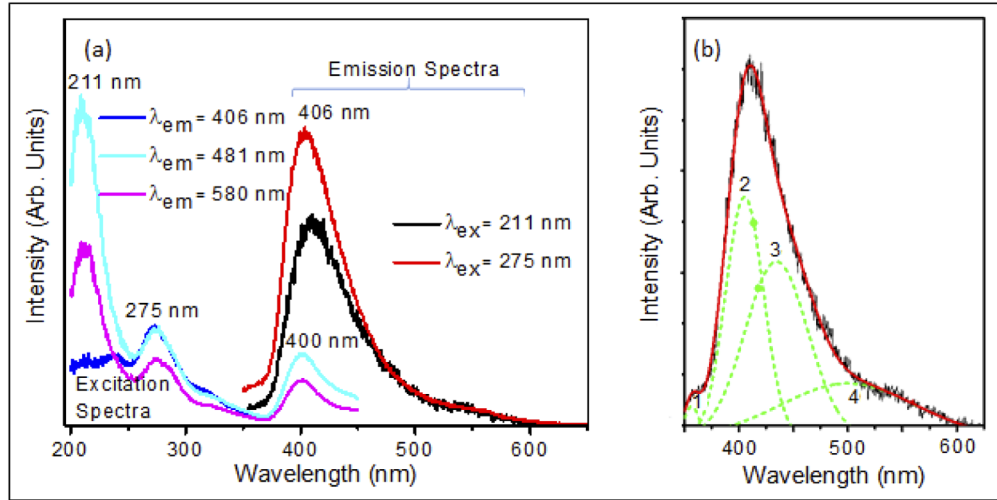

Fig. 6. (a) Excitation and emission spectra of the undoped sample (b) deconvoluted emission spectrum of the undoped sample.

band whose maxima is centered at 406 nm and the Dy^{3+} intra-configurational transition lines at 481 and 580 nm. The dominant 481 nm (blue) peak is ascribed to the hypersensitive electric dipole $(^4F_{9/2} \rightarrow {}^6H_{13/2})$ transition, while the yellow emission peak at 580 nm is assigned to magnetic dipole $(^4F_{9/2} \rightarrow {}^6H_{15/2})$ transition of Dy^{3+} [55,56]. The emission intensities of $^4F_{9/2} \rightarrow {}^6H_{13/2}$ transition in nanocomposite samples are greater than the $^4F_{9/2} \rightarrow {}^6H_{15/2}$ transition (Fig. 7(a)), showing very little deviation from an inversion symmetry [57]. According to Diaz-Torres et al., [55], the ratio between the intensities of these two peaks is known as the asymmetric ratio, *R*. *R* is used in determining the site symmetry or estimate the structural changes around the Dy^{3+} ions as well as the covalency of the bonds involving the oxygen ions. The asymmetry ratio, *R* for the composites was calculated using Eq. (5) [58];

$$R = \frac{\int I(^4F_{9/2} \rightarrow {}^6H_{13/2})dv}{\int I(^4F_{9/2} \rightarrow {}^6H_{15/2})dv} \tag{5}$$

where $\int I(^4F_{9/2} \rightarrow {}^6H_{13/2})dv$ and $\int I(^4F_{9/2} \rightarrow {}^6H_{15/2})dv$ are the integrated intensities of the hypersensitive transition and magnetic dipole transition, respectively.

Table 2 shows the calculated values of *R*, at the various concentrations of the Dy^{3+} doping in the nanocomposites. It has been shown that whenever the site occupied by the Dy^{3+} ions is highly symmetrical, the *R* value is low, whereas high values of *R* results from lower symmetry. Table 2 shows low values of *R*, (1.95–2.28) indicating a low symmetry around the Dy^{3+} sites in the nanocomposite, hence the electric dipole transition (blue) has the strongest intensity.

The intensities of the $^4F_{9/2} \rightarrow {}^6H_{13/2}$ and $^4F_{9/2} \rightarrow {}^6H_{15/2}$ transition peaks decreased with increasing Dy^{3+} concentrations indicating concentration quenching as a result of the shortened distance between activator ions (Dy^{3+} ions). At close proximity, energy is transferred among Dy^{3+} ions until it is absorbed by the lattice leading to the observed emission quenching. The critical distance, R_c is a threshold distance which defines the interaction mechanism of the concentration quenching and is defined by the relation [59];

$$R_c = 2\left(\frac{3V_x}{4\pi X_c N}\right)^{1/3} \tag{6}$$

Fig. 7. (a) Excitation spectra of the Dy^{3+}-doped samples at $\lambda = 481$ nm and (b) Emission spectra of the samples at $\lambda = 211$ nm.

Table 2. CIE coordinates and asymmetry ratio of nanocomposites

Sample	CIE Coordinates		CCT (K)	Colour Purity %	Asymmetry Ratio, R
	x	y			
0%	0.165	0.103	2734	81.9	-
1%	0.250	0.265	17025	34.4	2.14
2%	0.271	0.315	9581	22.3	2.06
3%	0.258	0.301	11516	27.9	2.16
4%	0.242	0.285	14974	34.6	1.95
5%	0.201	0.239	51318	52.9	2.28

where V_x is the unit cell volume; in this case 49.970 $Å^3$ for ZnO and 132.514 $Å^3$ for ZrO_2, N is the number of cationic sites available in the unit cell of the nanocomposite, in which $N = 4$ for both hexagonal ZnO and cubic ZrO_2. Finally, the critical concentration, X_c of the Dy^{3+} ions, is the concentration at which the luminescence intensity of sensitizer is half that of sample without the activator. Since Dy^{3+} ions were excited through the host excitation band wavelength at 211 nm (Fig. 7(b)), the emission from Dy^{3+} is as a result of the transfer of energy from the host to the activator (Dy^{3+}) ion. Therefore, the critical concentration, X_c was obtained by plotting the emission intensity verses the concentration of Dy^{3+} ions as shown in Fig. 8. From the figure, the point at which the Dy^{3+} concentration axis for the host emission intensity is half that of the sample without Dy^{3+} ion is the critical activator ion concentration and its value was found to be 0.64%. There are basically two energy transfer mechanisms responsible for the concentration quenching; the exchange interaction which takes place at short distances below 5 Å and multipole interaction at distances larger than 5 Å. The calculated R_c values are 15.5 Å and 21.4 Å for ZnO

and ZrO_2 in the nanocomposite, effectively ruling out the possibility of exchange interaction as the energy transfer process.

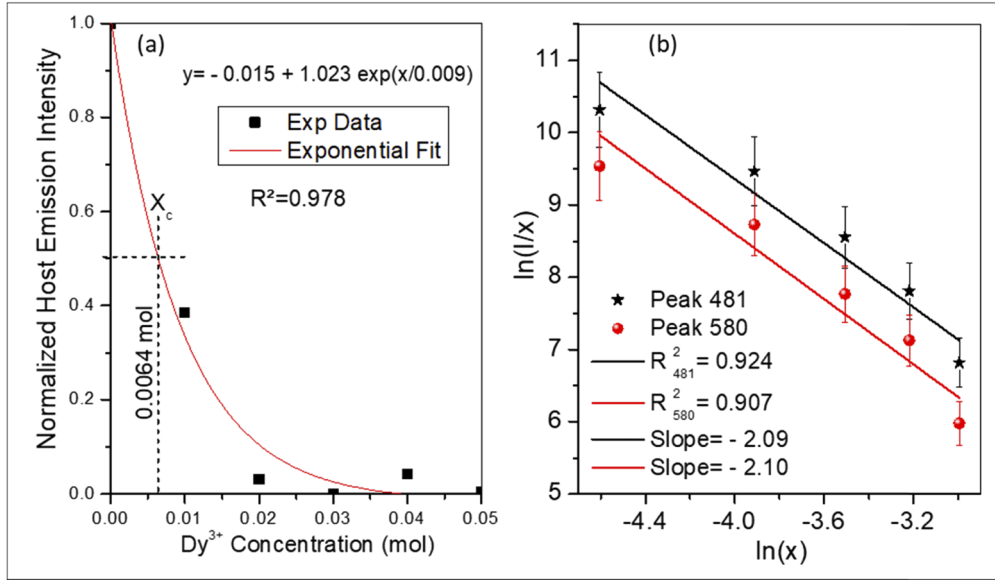

Fig. 8. (a) Dependence of the host emission band intensity on Dy^{3+} concentration and (b) fitting line of ln(I/x) versus ln(x) in nanocomposite.

According to Dexter's theory of energy transfer, [60–62], multipolar interaction can be determined by the relationship: -

$$\frac{I}{x} = k[1 + \beta \, (x)^{\theta/3}]^{-1} \tag{7}$$

where x is Dy^{3+} ion concentration (usually greater than the critical concentration, X_c), I/x is the emission intensity per concentration, k and β are constants dependent on the host lattice and θ is a function of multipolar character; whose values are $\theta = 6, 8, 10$ for dipole-dipole (d-d), dipole-quadrupole (d-q) and quadrupole-quadrupole (q-q) interactions, respectively. Using natural logarithms, Eq. (7) was reduced to a linear relationship and plotted in Fig. 8(b). From the equation, the slope of the linear fit of ln(I/x) verses ln(x) is equivalent to $-\theta/3$ and has values of -2.09 and -2.10 for the $^4F_{9/2} \rightarrow {}^6H_{13/2}$ (481 nm) and $^4F_{9/2} \rightarrow {}^6H_{15/2}$ (580 nm) transitions. Thus, θ was evaluated as 6.3, showing that the major energy transfer process responsible for the luminescence quenching in the nanocomposites was the dipole-dipole interaction between Dy^{3+} ions.

Therefore, the quenching at the high Dy^{3+} doping ratios is due to the energy transfer amongst the dopant ions arising from the reduced distances between the ions [63]. However, enhanced defect levels arising from the dopant oxygen vacancies, that act as charge traps in the lattice may lead to quenching [64]. The incorporation of Dy^{3+} ions in the composite may as well populate deep level non-radiative defects in the host matrix with enhanced doping.

Figure 9 shows the Commission International de I'Eclairage (CIE) coordinates [65] for the nanocomposites. From the PL spectra data, the chromaticity coordinates, the correlated colour temperature (CCT) and the colour purity of the Dy^{3+} doped composites were calculated at various concentrations and presented in Table 2. The coordinates of the undoped composite are in the violet region, while those of the doped samples are in the light blue region, with an advancement towards white light with enhanced doping. The CCT column in Table 2 shows that

higher temperature radiations are emitted from the surfaces having enhanced doping. This is in agreement with studies which have shown that dysprosium has a dominant emission in the blue region [66]. Due to the dependence of the emissions on the dopant concentrations, the phosphors can, therefore, be tuned for use as sensors and blue LEDs as well as efficient light applications such as display systems.

Fig. 9. CIE coordinate diagram of the composite showing the colours emitted at various doping percentages.

3.5.   Lifetime measurements

Luminescence decay analysis can be used to obtain the energy transfer and quenching mechanisms within a material. Figure 10(a) shows the decay lifetimes of the 481 nm Dy^{3+} emissions when the samples were excited at a wavelength of 211 nm while Fig. 10(b) shows the normalized half-log decay curves. The non- linearity of the half-log plot shows that the decay was multiexponential and hence subsequently fitted into a bi-exponential function. According to Kumari and Manam [58], a bi-exponential decay may be expressed as;

$$I(t) = I_0 + A_1 e^{-t/\tau_1} + A_1 e^{-t/\tau_2} \tag{8}$$

The average decay lifetime, $< t >$ is expressed as,

$$<t> = \frac{A_1 \tau_1{}^2 + A_2 \tau_2{}^2}{A_1 \tau_1 + A_2 \tau_1} \tag{9}$$

where *I(t)* is the luminescence intensity at time *t*, A_1 and A_2 are weighted constants, τ_1 and τ_2 are short and long decay components of the lifetimes, respectively. The long decay time is attributed to the dopant ions entrenched at the core of the crystallite site while the short decay time is associated with the dopant ions at the surface or near defect sites such as interstitials [67].
Fig. 10. (a) Normalized decay lifetime (b) half-log plot of decay lifetime of the nanocomposite.

Table 3 shows the average decay lifetimes $< t >$, of the doped samples. It was observed that the lower dopant ratios had higher lifetime values than the other samples. The reducing lifetimes on increased doping are an indication of non-radiative energy transfer from the host matrix to Dy^{3+} ions at or near the surface [67,68]. It can be concluded that the dopant ions segregated out onto the surface or interstitials in agreement with the XRD results and the decreased luminescence observed from enhanced doping.

Table 3. Average lifetimes of the samples excited at 211 nm to emit at a wavelength of 481 nm

Dysprosium conc./mol	0%	1%	2%	3%	4%	5%
Average lifetime $<t>$ (ms)	4.80	8.18	5.47	4.01	3.24	3.10

4. Conclusion

Dysprosium - doped zinc zirconate composites were synthesized successfully using the solution combustion route. In this synthesis, zirconium butoxide and citric acid fuel were used. The composite consisted of mixed phases of cubic zirconia and hexagonal zinc oxide nanocrystals. These composites showed a tunable energy band gap lying between 2.99 and 3.07 eV. The doped samples exhibited varied PL spectra with the major excitation and emission peaks observed at 211 nm and 481 nm, respectively. The synthesized phosphors emit in deep blue region advancing towards white light as the Dy^{3+} concentration increases. The nanocomposite phosphors can be used in sensors, LEDs and the display technology.
